16

Short title: Secondary zoospores of *Plasmodiophora brassicae*

17

1 **Abstract**

2 The disease cycle of *Plasmodiophora brassicae* consists of a primary phase in root hairs
3 followed by a secondary phase in the root cortex and adjacent tissues. However, the role
4 of root hair infection in subsequent cortical infection and development of *P. brassicae* is
5 not well understood. To examine the role of the primary and secondary stages separately,
6 inoculation studies with resting spores (source of primary zoospores) and secondary
7 zoospores of a virulent and avirulent pathotype were conducted on canola (*Brassica*
8 *napus*). The size of secondary zoospores and number of nuclei were also examined. The
9 zoospores were larger (~ 9.6-14.4 μm) than in previous reports and all were uni-nucleate.
10 Inoculation with secondary zoospores alone produced both primary and secondary
11 infection, even with the avirulent pathotype. No symptoms developed from inoculation
12 with avirulent primary zoospores, but tiny, bead-shaped clubs developed from inoculation
13 with avirulent secondary zoospores. Inoculation with virulent secondary zoospores alone
14 resulted in lower disease severity than inoculation with virulent resting spores alone. The
15 results indicate that recognition of infection by the host, and initiation of a response
16 (induction or suppression of resistance) occurs during primary infection, although
17 recognition can also occur during cortical infection and development.

18 **KEY WORDS:** clubroot, cortical infection, zoospores, resistance, canola

22

23

1 **Introduction**

2 *Plasmodiophora brassicae* Woronin, an obligate parasite causing clubroot, is an
3 emerging threat to canola (*Brassica napus* L.) production in Canada (21, 23) and across
4 the Northern Great Plains of the United States. The disease cycle of *P. brassicae* consists
5 of two phases, a primary phase that is restricted to root hairs and occasionally epidermal
6 cells, and a secondary phase that involves pathogen infection and proliferation within the
7 root and subsequent symptom development (24). In the primary phase, resting spores in
8 the soil germinate and release primary zoospores that penetrate root hairs to form primary
9 plasmodia. The primary plasmodia form multinucleate zoosporangia that produce uni-
10 nucleate secondary zoospores. This process takes about 5 days at the optimum
11 temperature of 25° C (38). The secondary zoospores are released into the soil solution,
12 infect root cortical cells, and develop into motile secondary plasmodia (10, 27). After a
13 mobile phase within the root, the young plasmodia coalesce into sessile vegetative
14 plasmodia that divide to form long-lived resting spores (10, 24, 27). Cortical infection
15 results in hyperplasia and hypertrophy of the root cells, which produces the characteristic
16 swollen, rounded clubbed root symptoms (24, 27). Clubbed roots are readily visible
17 within 5 to 6 weeks of inoculation at temperatures of 20–25° C (39).

18 The roles of primary and secondary infection in pathogenesis by *P. brassicae* are
19 not fully understood. Primary and secondary zoospores cannot be differentiated visually;
20 both are ovate with two whiplash flagella of unequal length (12,13, 24). Some authors,
21 and at least one authoritative pathology textbook, have concluded that secondary
22 zoospores fuse to form bi-nucleate zoospores prior to infecting the root cortex (2, 10, 24),

1 but observation of fusion has not been reported (10). Thus, it is still unclear whether
2 fusion of secondary zoospores is a necessary step prior to cortical infection.

3 Inoculation with resting spores initially produces only primary (root hair)
4 infection, but inoculation with secondary zoospores results in both primary and secondary
5 infection in susceptible hosts (12, 35). Primary infection occurs in both susceptible and
6 resistant host cultivars (6, 8, 15, 34). Primary infection can also occur in several non-host
7 species (34), but secondary infection and development of small numbers of resting spores
8 has been reported in only a few species that are generally considered non-hosts (33).

9 It is not known whether primary infection affects the initiation of resistance in
10 host species. However, recent studies indicate that non-host resistance to secondary
11 infection is induced initially during root hair infection. Inoculation of a non-host,
12 perennial ryegrass (*Lolium perenne* L.), with secondary zoospores resulted in secondary
13 infection and production of young plasmodia, but not mature plasmodia or resting spores
14 (12).

15 The predominant pathotypes of *P. brassicae* in Canada are pathotypes 2, 3, 5 and
16 6 (based on the differential set of Williams (45) and confirmed using the European
17 Clubroot Differential set (42, 43). Several pathotypes of *P. brassicae* are present on the
18 Canadian prairies, and more than one pathotype can be present in a field (4, 43, 46).
19 However, pathotype 3 is the predominant pathotype found on canola in the region (4).
20 Breakdown of resistance to *P. brassicae* has been documented in numerous Brassica
21 species (9, 32). Loss of genetic resistance is a concern for Canadian canola producers (23,
22 32), where resistance represents one of the most effective tools to manage clubroot (18).

1 The current study was conducted to assess the roles of infection by primary and
2 secondary zoospores in the initiation of susceptibility and resistance to *P. brassicae* in
3 canola. Experiments were conducted to compare both compatible (susceptible host) and
4 incompatible (resistant host) reactions of canola plants inoculated with primary and /or
5 secondary zoospores of virulent and avirulent pathotypes of *P. brassicae*. The treatments
6 were selected to permit evaluation of two competing hypotheses of disease reaction to
7 clubroot. One hypothesis was that primary infection suppresses initiation of resistance in
8 a susceptible cultivar and stimulates initiation of resistance in a resistant cultivar. The
9 alternative was that primary infection has no effect on initiation of resistance. In addition,
10 flagellate and encysted secondary zoospores were examined to determine whether they
11 were uni- or bi-nucleate and to confirm their morphology.

12

13 **Materials and Methods**

14 **Plant material, inoculum, and inoculation**

15 The canola cv. ‘Zephyr’ (AAFC, Saskatoon, SK, Canada) was selected for the study
16 because it is resistant to pathotype 6 (P6) of *P. brassicae* but susceptible to P3 (Deora,
17 unpublished). All plants were watered daily with demineralised water adjusted to pH 6.3
18 using commercial vinegar (5% acetic acid), and fertilized weekly with a nutrient solution
19 composed of 0.025% each of NPK (20:20:20, Plant Products Co. Ltd., Canada).

20 A field isolate of P3 was obtained from clubbed roots of canola grown in a
21 commercial field near Edmonton, AB, Canada, where P3 is predominant (42, 43). An
22 isolate of P6 (S. Strelkov, personal communication) was obtained from clubbed roots of
23 canola grown at the Muck Crops Research Station of the University of Guelph, Holland
24 Marsh, ON, Canada. Inoculum of each pathotype was increased prior to the study on the

1 highly susceptible Shanghai pak choy cv. Mei Qing Choy (Stokes Seeds, St. Catharines,
2 ON, Canada) under controlled conditions (40). The clubbed roots were stored at -20°C
3 prior to use.

4 Inoculum of resting spores was prepared based on the method of Jones et al. (26).
5 Briefly ~3 g of frozen clubs (swollen clubbed roots) were thawed at room temperature,
6 homogenized in 100 ml of water at high speed for 2 min, and the resulting spore
7 suspension was strained through eight layers of cheesecloth. The resting spore
8 concentration was determined using a haemocytometer and adjusted to 3×10^5 spores ml^{-1} .
9 Freshly prepared inoculum was used for each inoculation. Five-day-old seedlings were
10 inoculated by pipetting 5 ml of the spore suspension at the base of each seedling and
11 control plants were mock inoculated with deionized water.

12 Inoculum of secondary zoospores for an initial trial in cell culture plates was
13 produced using the method of Feng et al. (12) with only slight modification. Seed was
14 planted in $20\text{ cm} \times 20\text{ cm} \times 10\text{ cm}$ plastic trays filled with washed, autoclaved coarse
15 sand. Seven-day-old seedlings were inoculated with 500 ml of 1×10^8 resting spores ml^{-1} .
16 To avoid cross-contamination, separate trays were used for each pathotype. After 7 days,
17 about 4000 plants were uprooted and the roots were washed with tap water. The foliage
18 was then cut off near the hypocotyl, and the roots were further rinsed three times by
19 shaking at 150 rpm for 20 min in 200 ml of sterile deionized water in a 500 ml flask. The
20 roots (~1000 per flask) were shaken for 20 h in 50 ml deionized water at 100 rpm to
21 stimulate the release of secondary zoospores. After removing the roots, 10 ml of the
22 zoospores suspension was concentrated by centrifugation at 5000 g for 5 min and
23 adjusted to 1×10^6 zoospores ml^{-1} . Ten samples of this suspension were examined

1 microscopically to confirm that no resting spores were present in the suspension. The
2 concentration of secondary zoospores in the initial inoculum suspension was estimated
3 using a haemocytometer and adjusted to 3×10^5 spores ml^{-1} . The spore suspension was
4 then used immediately for inoculation.

5 For the study of symptom development, secondary zoospores were produced on
6 canola seedlings planted in Conetainers (plastic 21 cm \times 3.8 cm cones Conetainers,
7 Stuewe and Sons Inc., Corvallis, OR) filled with sand, thinned to five seedlings per cone,
8 and inoculated with 5 ml of 1×10^8 resting spores ml^{-1} per cone at 5 days after seeding
9 (DAS). The seedlings were washed and then planted directly into treatment cones as a
10 source of secondary zoospores at 7 days after the initial date of inoculation with resting
11 spores (12 DAS) (35). This approach was used because it was not possible to harvest the
12 large number of secondary zoospores required using the initial methodology.

13

14 **Primary and secondary infection**

15 Canola seed was sown into 24-well cell culture plates (Sigma Aldrich Canada Ltd.,
16 Oakville, ON, Canada) filled with sand. The plates were watered daily and maintained in
17 a growth room at 20°/25° C (day/night) with 75% relative humidity and a 16-h
18 photoperiod. After 5 days, the plates were thinned to one seedling per cell. Each
19 experimental unit consisted of a single seedling, and the study was arranged in a
20 randomized complete block design (RCBD), with four replicates at each of three
21 sampling dates. There were nine inoculation treatments: 1) resting spores (RS) of P3, 2)
22 RS of P6, 3) RS-P3@10 DAS, 4) RS-P6@10 DAS, 5) secondary zoospores (SZ) of P3,
23 4) SZ-P6, 5) RS-P3+SZ-P3, 6) RS-P6+SZ-P3, and 9) a control inoculated with sterile

1 water only. All of the resting spore treatments except those designated as ‘@10 DAS’
2 were applied to 5-day-old seedlings. Secondary zoospore treatments and the late (@10
3 DAS) resting spore treatments were applied to 10-day-old seedlings. Each seedling was
4 inoculated by pipetting 0.5 ml of 3×10^5 spores ml⁻¹ at the base of the seedling. At
5 optimum temperature for pathogen development, the primary phase of development is
6 nearly complete and secondary zoospores are released at about 5 days after inoculation
7 (39, 40). Therefore, secondary zoospores were applied 5 days later than the primary
8 zoospores to ensure that, as much as possible, secondary infection in all of the treatments
9 occurred at the same time, and that the seedlings were at a uniform developmental stage
10 when secondary infection occurred. The late inoculation treatments with resting spores
11 were included to provide an inoculated control for treatments at 10 DAS.

12 Four seedlings per treatment were destructively sampled at 11, 13 and 15 days
13 after seeding (1, 3, and 5 days after application of the secondary zoospores and late
14 application of resting spores). The root of each seedling was separated from the foliage,
15 washed in running water, and placed individually in 2-ml centrifuge tubes containing a
16 fixative solution of 50% ethanol. Five fields of view along a 2-cm-long root segment
17 from each taproot were assessed using a compound microscope with a 10x objective lens
18 (39). In each field of view, the incidence of root hair infection and secondary plasmodia
19 in cortical tissue were counted based on the method of Feng et al. (12).

20

21 **Symptom development**

22 Seeds of canola cv. ‘Zephyr’ were planted in Conetainers filled with soil-less mix
23 (Sunshine mix # 4, Sun Gro Horticulture Canada Ltd, Spruce Grove, AB). A 5-ml pipette

1 tip was inserted into the soil-less mix in the centre of the pot. The seedlings were thinned
 2 to one per pot after 5 days. The same nine treatments described previously were
 3 examined in a RCBD with four replicates and 10 plants per replicate. The main group of
 4 resting spore suspension treatments (5 ml, 3×10^5 spores ml⁻¹) were applied to 5-day-old
 5 seedlings and secondary zoospore treatments were applied to 10-day-old seedlings, as in
 6 the initial trial. However, secondary zoospores were applied by removing the 5 ml pipette
 7 tip from each pot and planting five infected seedlings into the cavity created by the
 8 pipette tip (36). Non-inoculated plants were used as a control. The seedlings used for
 9 inoculation were removed after 5 days.

10 The plants were harvested 52 days after seeding, which was 42 days (6 wks) after
 11 inoculation with secondary zoospores. Plant height above the hypocotyl was measured
 12 and the roots were washed and assessed for clubroot incidence and severity, based on
 13 visual symptoms of root clubbing. The plants were separated into classes using a standard
 14 0–3 scale, where 0 = no clubbing, 1 < 1/3 of the root with symptoms of clubbing, 2 =
 15 1/3–2/3 clubbed, and 3 > 2/3 clubbed (31). A disease severity index (DSI) was calculated
 16 using the following equation (43):

$$\text{DSI} = \frac{\sum [(\text{class no.})(\text{no. of plants in each class})]}{(\text{total no. plants per sample})(\text{no. classes} - 1)} \times 100$$

17

18 Each root was then prepared, sectioned, and stained, and the intensity of cortical
 19 infection was assessed using the method of Sharma et al. (39). A segment (0.5-cm-long)
 20 was cut from the top 0–1 cm of each taproot, dehydrated through an ethanol series, and a
 21 4-µm-thick cross-section was cut using a microtome. The sections (one per root, four per

1 treatment) were placed on a microscope slide and stained in 0.5% methylene blue for 5
2 min. Development of *P. brassicae* was assessed based on the presence of key
3 developmental stages: i) secondary plasmodia, ii) vegetative plasmodia, and iii) resting
4 spores . The number of cells that contained plasmodia or resting spores in each
5 microscope field (10x objective lens) were counted in five fields of view per section.
6 Cortical infection was assessed using image analysis, by estimating the area (%) occupied
7 by plasmodia and resting spores in digital images of each field of view (10x objective
8 lens) using image analysis software (Assess version 2.0, American Phytopathological
9 Society, St. Paul, MN). A total of 20 fields of view were assessed per treatment in the
10 trial. The trial was repeated.

11 To observe the location and extent of lignification, another set of 4- μ m-thick
12 cross-sections (one per root, four per treatment) was placed on a microscope slide and
13 stained with 1% toluidine blue O (TBO) for 3 min. These roots were examined using a
14 compound microscope following the method of Deora et al. (7). Lignified areas stained
15 blue and pectic substances stained pink-purple (36).

16

17 **Infectivity of resting spores from bead-shaped clubs**

18 A study was conducted to determine if the resting spores produced in bead-shaped clubs
19 were infectious. In those treatments where bead-shaped clubs developed, the tap root and
20 lateral roots were collected, washed, diced into small pieces and used to inoculate 5-day-
21 old seedlings, with pieces from two roots applied to each seedling. Roots of non-
22 inoculated seedlings (negative control) and plants that had been inoculated with resting
23 spores of P6 (positive control) were also assessed. The inoculated plants were harvested 6

1 wk after transplanting and assessed for clubroot incidence and severity as described previously. The trial was laid out in a RCBD with four replicates and 10 plants per replicate. The trial was repeated.

4

5 **Nuclear visualization**

6 The nuclei of zoospores forming within root hairs were stained and photographed.
7 Seedlings of the susceptible canola cv. 46A76 (Pioneer Hi-Bred, Caledon, ON) were
8 grown at 24/20 °C in Conetainers filled with autoclaved (121° C for 30 min) sand. A 5-
9 ml suspension of 1×10^6 resting spores ml^{-1} of P6, prepared as described previously, was
10 applied at the base of each 8-day-old seedling; the control received water only. There
11 were three replications with three plants per replicate. Plants were watered every day as
12 required. The roots were harvested at 12 days after inoculation and preserved in ethanol:
13 acetic acid (3:1) solution. The harvested roots were stained with Hoechst 33258
14 (bisbenzimidazole H, Sigma-Aldrich Canada Ltd.) at 20 $\mu\text{g/ml}$ and observed under an upright
15 Leica DM 6000B confocal laser scanning microscope (CLSM) (Leica Microsystems,
16 Concord, ON Canada). Only root hairs that contained the zoosporangial stages of primary
17 infection were targeted to observe the nuclei of secondary zoospores. An excitation
18 wavelength of 405 nm and an emission and detection channel of 427–490 nm were used.
19 To produce a fluorescence image, averaging (oversampling) was conducted. For Z-
20 sectioning, 10 to 30 sections were obtained, depending on the depth of the sample. For
21 the overlaid image of fluorescence and differential interference contrast (DIC) presented,
22 the thickness of the sample was 35 μm , for which 85 sections were obtained at a step size
23 of 0.42 μm .

1 To stain the nuclei of flagellate zoospores, 100 μ l of secondary zoospores
2 suspension (produced as described previously) was placed on a lysine-coated glass-
3 bottomed culture dish (14-mm-diam., MatTek Corporation, MA). The zoospores were
4 fixed by adding 100 μ l of 2% glutaraldehyde. Zoospores were allowed to settle on the
5 bottom of the dish for 30 min, rinsed three times in phosphate buffer (pH 6.8) at 2 min
6 intervals, stained for 1 min with DAPI (4'-6-diamidino-2-phenylindole, 1 μ g/ml water,
7 Sigma-Aldrich Canada Ltd.), rinsed with buffer, and mounted on a glass slide in 50%
8 glycerol with 0.1% p-phenyldiamine. The number of nuclei in each zoospore was
9 assessed using epifluorescence microscopy with a blue filter (wide band UV); excitation
10 band pass 360–385 nm (dichromatic beam splitter DM400) and emission barrier filter
11 420 nm (Olympus BX60F5 microscope, Olympus Optical Co. Ltd., Japan).

12 For nuclear staining of encysted zoospores, 5 ml of the secondary zoospore
13 suspension was concentrated by centrifugation at 5000g for 5 min, and then assessed as
14 described above. At least 25 flagellate or encysted zoospores were observed in each
15 assessment and the study was repeated.

16 The size of secondary zoospores produced and held in various solutions was
17 assessed. After harvesting the roots for secondary zoospore production as described
18 above, roots were incubated in a shaker in either deionized water, phosphate buffer
19 (Na_2HPO_4 and NaH_2PO_4 ; Sigma-Aldrich, St. Louis, MO) or sodium chloride
20 physiological solution (Sigma). The pH of the phosphate buffer and physiological saline
21 was adjusted to 7.0 with NaOH (Sigma). After 20 h of incubation, a suspension of
22 swimming or encysted zoospores (obtained by vortexing for 1 min) from each solution
23 was fixed with 1% glutaraldehyde. The length and width of 30 fixed zoospores from each

1 solution were measured on photos taken using a stereo binocular microscope (Nikon
2 Eclipse 5.1, Nikon Corporation, Japan).

3

4 **Statistical analysis**

5 There were two repetitions of each experiment investigating infection and symptom
6 development. A general linear model analysis of variance was conducted using Proc
7 GLM of SAS version 9.1 (SAS Institute, Inc., 2010, Cary, NC). Prior to analysis, root
8 hair infection (RHI, %), clubroot incidence (%), clubroot severity (disease severity index,
9 DSI), and area of cortical infection (%) data were arcsine transformed to improve the
10 normality and homogeneity of variance, but non-transformed means are presented for
11 uniformity of presentation. There was no repetition effect or repetition \times treatment
12 interaction for any response variable, so the repetitions of each trial were pooled for
13 subsequent analysis. Means separation was conducted using Tukey's test at $\alpha \leq 0.05$. The
14 correlation between cortical colonization and disease severity index was examined using
15 Pearson's correlation coefficient in Proc Corr of SAS.

16 In the infection and symptom development trials, a few specific comparisons were
17 particularly important for hypothesis testing. Comparison of RS-P6 with SZ-P6 provided
18 a measure of the role of primary infection in initiation of resistance to an avirulent
19 pathotype. Similarly, comparison of RS-P3 with SZ-P3 provided a measure of the role of
20 primary infection in suppression of resistance to a virulent pathotype. Comparison of RS-
21 P6+SZ-P3 vs. RS-P3+SZ-P3 provided a measure of the role of early initiation of an
22 incompatible host reaction (P6) or a compatible reaction (P3) prior to secondary infection
23 and subsequent development of the virulent pathotype (SZ-P3). Similarly, comparison of

1 RS-P6+SZ-P3 with SZ-P3 provides a measure of the impact of early initiation of
2 resistance on subsequent development of a virulent pathotype, and comparison of RS-
3 P3+SZ-P3 with SZ-P3 provides a measure of the impact of early suppression of
4 resistance on subsequent development of a virulent pathotype.

5

6 **Results**

7 **Primary infection**

8 Each of the inoculation treatments resulted in root hair infection (RHI, Table 1). At 13
9 and 15 DAS (3 and 5 days after inoculation), RHI was higher following inoculation with
10 SZ-P3 compared to SZ-P6. Substantial levels of infection were first observed at 1 day
11 after inoculation in plants inoculated with RS-P3+SZ-P3 (63%), RS-P3 (46%) and RS-
12 P6+SZ-P3 (35%). At 15 DAS (5 days after inoculation), RHI was relatively high for all
13 of the treatments except RS-P6@10 DAS (26%), although differences among treatments
14 were still evident. RHI was higher for RS-P3 than RS-P6 and higher for SZ-P3 than SZ-
15 P6. RHI with RS-P3+SZ-P3 was higher than RS-P3 alone.. However, RHI was higher
16 with RS-P3+SZ-P3 than RS-P6+SZ-P3.

17 The incidence of RHI increased over time. There was a small inoculation
18 treatment x sampling date interaction ($F=148.5$, $P = 0.0001$, as compared to $F= 5308$ for
19 sampling date and 2249 for treatment), but inoculation treatment generally continued to
20 exhibit a similar pattern of response at the later assessment dates to that observed at 11
21 DAS.

22

1 **Secondary infection**

2 The most important differences in this study were observed in infection of the root cortex
3 (Fig. 1) and subsequent symptom expression (Table 2). Substantial numbers of plasmodia
4 in the root cortex were observed at 11 DAS in plants inoculated with RS-P3+SZ-P3 (15
5 secondary plasmodia) and RS-P3 (10 secondary plasmodia). Plasmodia were first
6 observed at 13 DAS in plants inoculated with RS-P3@10 DAS and SZ-P6, and at 15
7 DAS in plants inoculated with RS-P6@10 DAS. Plasmodia produced from primary and
8 secondary zoospores were similar in morphology (Fig. 2 A, B).

9 By 15 DAS, the differences among treatments were even more distinct than at the
10 earlier assessment dates (Fig. 1). As expected, inoculation with RS-P3 resulted in many
11 more secondary plasmodia per field of view (mean of 24 plasmodia per field) than RS-P6
12 (12 plasmodia). Inoculation with secondary zoospores alone resulted in fewer plasmodia
13 than resting spores of the same pathotype; 12 plasmodia for RS-P6 vs. 9.5 plasmodia for
14 SZ-P6, and 24 plasmodia for RS-P3 vs. 16 plasmodia for SZ-P3. RS-P3+SZ-P3 resulted
15 in more plasmodia (30 plasmodia) than either SZ-P3 alone (15 plasmodia) or RS-P3
16 alone (24 plasmodia). RS-P6+SZ-P3 resulted in fewer plasmodia than RS-P3+SZ-P3 (15
17 vs. 30). There were no differences in the number of plasmodia when SZ-P3 was applied
18 alone or in combination with RS-P6.

19

20 **Symptom development**

21 The pattern of symptom development and the extent and development of cortical
22 infection were evaluated at 52 DAS. The area of cortical infection, clubroot severity, and
23 the number of cells containing resting spores all showed the same pattern of response to

1 inoculation treatment (Table 2). The area of cortical colonization and the disease severity
2 index were highly correlated ($r = 0.92$; $P < 0.0001$). These trends were similar to that of
3 early (15 DAS) cortical infection above, except that no symptoms developed on plants
4 inoculated with RS-P6, even though some plasmodia had developed by 15 DAS and
5 young plasmodia were still visible at 47 DAS (22 infected cells per field of view).

6 In both the compatible and incompatible interactions, inoculation with resting
7 spores elicited a different pattern of response than inoculation with secondary zoospores
8 (Table 2). Inoculation with RS-P3 resulted in the highest values for both area of cortical
9 infection (33%) and number of cells with resting spores (32 cells), and 100% clubroot
10 incidence and severity. SZ-P3 produced less cortical infection (12%) and lower incidence
11 and severity (78% and 67% DSI) than RS-P3. The opposite pattern was observed in the
12 incompatible interaction; inoculation with RS-P6 produced 0% clubroot incidence (no
13 symptoms), but inoculation with SZ-P6 produced low levels of cortical infection (4%)
14 and development of resting spores (2 cells). Clubroot symptoms developed following
15 inoculation with SZ-P6, with a low incidence and severity consisting solely of small
16 bead-shaped clubs.

17 RS-P3+SZ-P3 produced 100% incidence and severity and the highest cortical
18 infection and number of cells with resting spore, the same as RS-P3 alone (Table 2).
19 However, RS-P6+SZ-P3 resulted in reduced levels of pathogen development in the root
20 cortex: incidence and severity were lower (85% and 86% DSI), as was the area of cortical
21 infection (18%) and number of cells with resting spores (26 cells). The only unusual
22 result was the comparison of SZ-P3 with RS-P6+SZ-P3. Inoculation with RS-P6+SZ-P3

1 resulted in higher area of cortical infection, more resting spores, and higher clubroot
2 severity than SZ-P3 alone.

3 No clubs developed on plants inoculated with RS-P6 or on the non-inoculated
4 control (Table 2). Typical large clubs developed on all of the other treatments. The only
5 exception was SZ-P6, where tiny, bead-shaped clubs developed in strings or clusters
6 along the root (Fig. 2C, D, E). Resting spores were present in the infected cortical cells of
7 the bead-shaped clubs (Fig. 3F). About 20 plants were assessed after an additional 2 wk
8 of growth (8 wk after inoculation), and the size and shape of the clubs had not changed.

9 Plant height and shoot weight were generally highest, and root mass and clubroot
10 incidence and severity were lowest, in plants with no clubbing (inoculated with RS-P6 or
11 controls) or with bead-shaped clubs (SZ-P6), intermediate with RS-P6+SZ-P3 and SZ-P3,
12 and lowest / highest in plants with large clubs (RS-P3 and RS-P3+SZ-P3) (Table 2).
13 Similarly, the root biomass of plants inoculated with RS-P6 (1.1 g) and SZ-P6 (1.4 g)
14 were similar, but only SZ-P6 produced clubroot symptoms, although the bead-shaped
15 clubs were considerably smaller in size and weight than typical clubs (Table 2).

16 Proliferation of *P. brassicae* resulted in severe distortion of root growth and
17 development (Fig. 3). In cross-sections of the roots of control plants, the periderm, cortex
18 and stele region were organised and continuous (Fig. 3A, B). In plants inoculated with
19 RS-P6, young plasmodia were observed in the cortical cells and stele, but the pathogen
20 did not develop further (Fig. 3C, D). As a result, plants inoculated with RS-P6 did not
21 differ morphologically from the controls. Typical clubs developed from inoculation with
22 RS-P3, RS-P3+SZ-P3, SZ-P3, and RS-P6+SZ-P3, but the clubs from inoculation with
23 SZ-P3 and RS-P6+SZ-P3 were smaller than normal. In all of the typical clubs, cortical

1 cells of the infected roots became enlarged and intermingled with the secondary phloem,
2 and the distinct organization of tissues into cortex, endodermis and stele was lost (Fig.
3 3G, H). The area occupied by cells with walls that stained for lignin in the stele decreased
4 rapidly during pathogen colonization (Fig. 3G, H).

5 In the bead-shaped clubs, cortical cells were highly plasmolysed and the stele was
6 continuous (Fig. 3E, F). The pathogen did not penetrate into the stele. As a result there
7 was limited cell proliferation in these tissues (Fig. 3F). Plants inoculated with resting
8 spores from the bead-shaped clubs became heavily infected and produced large clubs.

9

10 **Nuclear visualization**

11 Zoosporangia were present in most of the infected root hairs at 12 days after inoculation.
12 In mature zoosporangia, the plasmodial cytoplasm was cleaved to produce individual
13 zoosporangia (Fig. 4A). CLSM observation showed that these zoosporangia were multi-
14 nucleate and each nuclei reflected production of uni-nucleate incipient secondary
15 zoospores within the root hairs. Depending on the size, 1–6 nuclei were present in a
16 zoosporangium ($n = 20$) and the nuclear size varied from 1.0 to 1.5 μm ($n = 50$) (Fig.
17 4A).

18 The flagellate secondary zoospores collected in deionized water had a mean
19 length of $14.4 \mu\text{m} \pm 0.19$ and width $9.6 \mu\text{m} \pm 0.32$ ($n = 55$), and all had two anterior
20 whiplash flagella (Fig. 4B). The mean diameter of encysted zoospores (Fig. 4D) obtained
21 by centrifugation was $21.7 \mu\text{m} \pm 0.37$ ($n = 50$). All of the flagellate and encysted
22 zoospores were uni-nucleate (Fig. 4C, 4D). Secondary zoospores that were released into
23 phosphate buffer or physiological saline were slightly smaller than those produced in

1 deionized water. The length and width of flagellate zoospores in phosphate buffer were
2 $12.5 \mu\text{m} \pm 0.23 \times 8.7 \mu\text{m} \pm 0.25$ and in physiological saline were $11.8 \mu\text{m} \pm 0.29 \times 8.3$
3 $\pm \mu\text{m} 0.30$. The diameters of encysted zoospores in phosphate buffer and physiological
4 saline were $17.8 \mu\text{m} \pm 0.28$ and $17.3 \mu\text{m} \pm 0.44$, respectively.

5

6

7 **Discussion**

8 This is the first study to compare the roles of primary and secondary infection in both
9 compatible and incompatible reactions between *P. brassicae* and a host. We provide
10 evidence that root hair infection by *P. brassicae* plays an important role in host
11 recognition of the pathogen and influences the development of the pathogen at the
12 cortical infection stage. Canola cv. Zephyr was chosen because it is susceptible to
13 pathotype 3 (compatible reaction) and resistant to pathotype 6 (incompatible reaction);
14 these reactions were consistent across the trials. The severity of clubroot symptoms (DSI)
15 exhibited the same pattern of response as the extent of secondary infection of the root
16 cortex and the number of cells with resting spores, so these are the assessments that the
17 discussion will focus on.

18 Inoculation with RS-P6 (resting spores of pathotype P6, avirulent on cv. Zephyr)
19 resulted in no symptoms and very limited development of the pathogen, as expected in an
20 incompatible interaction. Inoculation with RS-P3 (resting spores of P3, virulent on cv.
21 Zephyr) resulted in the greatest symptom development and highest number of cortical
22 cells containing resting spores. This was as expected in a compatible reaction (6, 13, 17).
23 Inoculation with secondary zoospores of P6 alone (SZ-P6) resulted in much more cortical

1 infection than with RS-P6, while inoculation with SZ-P3 alone resulted in less cortical
2 infection than RS-P3. Comparison of the effect of inoculation with resting spores vs.
3 secondary zoospores on cortical infection and DSI provided a measure of the role of
4 primary infection in initiation of resistance or susceptibility. These results demonstrate
5 that primary infection plays a role in subsequent cortical infection in both compatible and
6 incompatible reactions. Cortical infection was almost completely suppressed after
7 primary infection with an avirulent pathotype (RS-P6), but the root cortex was infected
8 and colonized to a substantial extent with secondary zoospores of an avirulent pathotype
9 (SZ-P6). This indicates that primary infection with P6 induced a resistance response that
10 was most strongly expressed in the root cortex, although there was also a small effect on
11 pathogen development in root hairs. Conversely, cortical infection following primary
12 infection with a virulent pathotype (RS-P3) was more extensive than with secondary
13 zoospores of a virulent pathotype (SZ-P3) alone, which indicates that primary infection
14 induced susceptibility or suppressed resistance in the root cortex.

15 Comparison of RS-P6+SZ-P3 vs. RS-P3+SZP3 or SZ-P3 provided a measure of
16 the impact of early initiation of a resistance reaction on subsequent development of a
17 virulent pathotype. Inoculation with RS-P6+SZ-P3 resulted in less infection and lower
18 severity than RS-P3+SZP3 or SZ-P3. This response provides additional support for the
19 hypothesis that primary infection has a role in inducing resistance in an incompatible
20 reaction. In fact, it provides evidence that primary infection is an important step in
21 recognition of the avirulent pathogen. Similarly, comparison of RS-P3 vs. RS-P3+SZ-P3
22 or SZ-P3 alone provided a measure of the impact of early suppression of resistance on
23 subsequent development of a virulent pathotype in the compatible reaction. Inoculation

1 with RS-P3 produced more cortical infection and higher severity than SZ-P3 alone, but
2 the same level of symptom expression and cortical infection as RS-P3+SZ-P3. This
3 indicates that primary infection results in a slight but potentially important suppression of
4 host defences in a susceptible host.

5 Inoculation with SZ-P6 resulted in infection of the root cortex and pathogen
6 development sufficient to produce viable resting spores. However, symptom development
7 was restricted to small, bead-like clubs. This indicates that if recognition of the avirulent
8 pathotype does not occur at the primary infection stage, initiation of a resistance response
9 was delayed but not completely suppressed.

10 Inoculation with RS-P3 and RS-P3+SZ-P3 resulted in the maximum possible
11 level of clubroot severity (100 DSI) and the greatest area of cortical infection, which
12 might represent the maximum that can occur in this host-pathogen interaction. The initial
13 inoculation with 5 ml of 10^5 ml^{-1} of resting spores may have been sufficient to produce
14 100 DSI. Indeed, there are other reports of 100% clubroot severity with similar (5 ml of 1
15 $\times 10^6 \text{ ml}^{-1}$) concentrations of inoculum (7, 8. Repeating this comparison with a lower
16 inoculum concentration might help to elucidate the role of primary infection in a
17 compatible interaction.

18 The only result that did not support a role for primary infection in the initiation of
19 a resistance reaction in the host was the comparison of RS-P6+SZ-P3 vs. SZ-P3. If
20 primary infection by an avirulent pathotype stimulates the early initiation of host
21 resistance, inoculation with RS-P6 before adding SZ-P3 would be expected to suppress
22 infection and symptom development compared to secondary zoospores alone. However,
23 the reverse was observed. There was slightly more cortical infection with RS-P6+SZ-P3

1 than with SZ-P3 alone (18% vs. 12%), more cells with resting spores (15 vs. 12 cells) and
2 higher clubroot severity (84 vs. 67 DSI). This may indicate that primary infection has a
3 larger role in suppressing host defences than in stimulating resistance. However,
4 additional work in this area is required.

5 Most physiological and molecular studies on clubroot have focused only on the
6 compatible relationship, and indicate that fewer physiological changes occur in the host
7 during the primary phase of the pathogen's lifecycle compared with the secondary stage
8 (3, 41). However, none of the effectors that mediate compatible and incompatible
9 relationships with *P. brassicae* have been identified or characterized. During infection in
10 many host-pathogen systems, the pathogen secretes effectors that interact with the host
11 and play an important role in virulence and/or the stimulation of a resistance
12 (incompatible) response (16, 20, 25, 28). To establish a successful infection, *P. brassicae*
13 must either suppress host resistance or fail to trigger host resistance. In either case, the
14 response is likely triggered by effectors. In nonhosts, *P. brassicae* triggered a resistance
15 response (33), but root hair infection was critical for induction of resistance to secondary
16 infection and subsequent club formation (12).

17 In a recent study of gene expression in primary and secondary zoospores of
18 *P. brassicae*, many more genes were up-regulated in primary zoospores than in secondary
19 zoospores (14). The authors suggested that the genes that were up-regulated in secondary
20 zoospores likely contribute to infection of cortical tissue. The results of the present study
21 support their hypothesis that there are specific mechanisms required for secondary
22 infection, in that secondary zoospores can infect the root cortex in the absence of primary

1 infection, but primary infection has an important role in the recognition of a compatible
2 or incompatible pathotype.

3 The results of the current study are also consistent with the results of a study
4 conducted to identify changes in host gene expression in *Arabidopsis thaliana* (L) Heynh
5 inoculated with the compatible *P. brassicae* ecotype Co-1 (1). At 4 days after inoculation
6 (which corresponds to primary infection), expression of several genes known to be
7 involved in pathogen recognition and signal transduction was induced. Also, many more
8 host genes were down-regulated than were up-regulated. Some of the down-regulated
9 genes were involved in lignin and salicylic acid biosynthesis, the oxidative burst
10 pathway, and several other defence-related genes. In general, these results support the
11 hypothesis that primary infection suppresses host resistance. They are also consistent
12 with a recent study that identified that a compatible *P. brassicae*/canola interaction is
13 characterized by a lack of the reactive oxygen species and a reduction in lignin relative to
14 an incompatible interaction (6).

15 Infection and development of *P. brassicae* in the root cortex of susceptible and
16 resistant cultivars has been studied in detail (6, 7, 11, 17, 19, 30). Clubroot resistance was
17 expressed most clearly and consistently in the root cortex, where pathogen development
18 occurred quickly in susceptible cultivars. Very little or no pathogen development was
19 observed in highly resistant radish (30) and canola cultivars (6). In the current study,
20 plasmodia were observed in the root cortex of plants inoculated with resting spores of the
21 avirulent pathotype, but these did not develop to produce resting spores and no clubs
22 developed on the roots. This is consistent with recent studies showing that resistance can

1 be expressed after some initial colonization of the root cortex in canola (7) and cabbage
2 (17).

3 The present study provides some insights into the timing of the interaction
4 between effectors from *P. brassicae* and the host. Plants inoculated with resting spores of
5 the avirulent pathotype (P6) did not develop clubs, while direct inoculation with the
6 secondary zoospores of P6 resulted in infection and development of small bead-shaped
7 clubs. This indicates that the initial recognition of the pathogen normally occurs during
8 primary infection, so that the host is able to respond with effective resistance mechanisms
9 when challenged by secondary zoospores. Direct inoculation with secondary zoospores
10 either bypassed this recognition stage or did not provide enough time for the resistance
11 reaction to develop fully. However, the results of this study also showed that recognition
12 of the pathogen can occur during cortical infection and subsequent development of the
13 pathogen. Inoculation with secondary zoospores of the incompatible pathotype (P6)
14 resulted in lower levels of pathogen development than inoculation with secondary
15 zoospores of the compatible pathotype (P3), which in turn was lower than from
16 inoculation with resting spores of P3.

17 The small, bead-shaped clubs produced by secondary zoospores of P6 in this
18 study appear to be similar to the spheroid galls reported in resistant reactions by Williams
19 (45) and others (29). There is some disagreement in the literature as to whether this is a
20 true resistance response. Rennie et al. (38) point out that several researchers considered
21 these an indication of host resistance because the spheroid clubs (galls) represent a
22 restriction of the pathogen within the host. However, the authors suggest that the
23 formation of spheroid clubs should not be interpreted as complete resistance, since small

1 numbers of resting spores can develop in these clubs. The results of the current study
2 support the conclusion that this reaction does not represent complete resistance. Instead,
3 small clubs are produced when pathogen development is limited after some development
4 has already occurred in the root cortex. This in turn indicates that some component(s) of
5 host resistance was/were bypassed or delayed. Similarly, bead-shaped clubs were
6 observed on canola inoculated with secondary zoospores produced on a non-host (12).
7 This further supports the hypothesis that direct infection by secondary zoospores
8 bypasses recognition by the host during primary infection. However, clubbing symptoms
9 do not develop fully, likely because initiation of resistance is delayed or effectors at the
10 primary infection stage are required to allow a fully compatible interaction.

11 Differences in the incidence and development of primary infection of resistant and
12 susceptible host cultivars have been studied in detail (6, 11,). The results of the current
13 study support the observation that both virulent and avirulent pathotypes can infect root
14 hairs, but that the incidence of primary infection is higher in plants inoculated with
15 virulent pathotypes than with the avirulent pathotypes (6, 22). The present study also
16 confirms previous reports that secondary zoospores of *P. brassicae* can initiate both
17 primary and secondary infection (12, 13, 35).

18 Secondary zoospores were examined for the presence of bi-nucleate zoospores
19 because there were reports that bi-nucleate zoospores of *P. brassicae* result from fusion
20 of two zoospores (5, 44) and that cortical infection occurs after the secondary zoospores
21 fuse in pairs (10, 24). In the current study, all of the secondary zoospores were uni-
22 nucleate, which indicates that the majority of secondary zoospores do not fuse. Further
23 study into this phase of the life cycle is warranted. If fusion of secondary zoospores was

1 a prerequisite to cortical infection, this would greatly reduce the effective inoculum
2 concentration. The secondary zoospores in this study were morphologically identical to
3 primary zoospores (oval shaped, with one nucleus and two flagella of uneven length), as
4 has been reported in previous studies (12, 13, 27).

5 The average size of secondary zoospores released in deionized water after
6 mechanical shaking of the roots was 9.6 μm x 14.4 μm , while those released into
7 phosphate buffer were slightly smaller. Secondary zoospores observed within root hairs
8 were reported to be much smaller, 2.5 μm x 3.5 μm (24) or 1.5 x 0.5-0.7 μm (5).
9 Differences in the size of secondary zoospores were also observed when they were
10 switched from 10% glucose solution to water (Feng, unpublished). Since the zoospores in
11 the present study were released in deionized water, it is highly likely that they would take
12 up more water and swell to a larger size than those in a buffer or an ionized solution.
13 Secondary zoospores within a root hair are likely smaller than released zoospores as a
14 result of higher osmotic or physical pressure in the root hairs. This is the first report of
15 the size of free living secondary zoospores.

16 The methods used to produce and collect secondary zoospores were those of Feng
17 et al. (12). This method has several advantages over using infected plants as a source of
18 secondary zoospores, since the inoculum concentration can be quantified and adjusted as
19 required. However, it proved to be difficult to consistently obtain large quantities of
20 secondary zoospores, so infected seedlings were used as a source of secondary zoospores
21 (35) for some of the studies. The results using this approach were consistent between
22 repetitions of the study and exhibit a similar pattern of response to studies using collected

1 secondary zoospores, so we conclude that this is a suitable inoculation approach for use
2 in future studies.

3 In summary, this is the first study to demonstrate that the primary infection phase
4 of *P. brassicae* plays an important role in host recognition of the pathogen. The results
5 support the hypothesis that primary infection suppresses the initiation of resistance in a
6 susceptible cultivar and also stimulates the resistance reaction in a resistant cultivar. It
7 appears likely that pathogen effectors are recognized at the primary infection stage and
8 that this early interaction between host and pathogen contributes to the resistant or
9 susceptible reaction in the host at the secondary infection stage. Induction of
10 susceptibility was more effective than initiation of resistance in the two pathotype/host
11 interactions examined. Recognition of the pathogen as compatible or incompatible also
12 occurred in the root cortex, but the resistance reaction developed more quickly and was
13 expressed more strongly in response to primary infection. Our results were consistent
14 with independent studies of gene expression in the pathogen and host in a compatible
15 interaction. However, additional study at the molecular level is needed to further
16 elucidate the role of primary and secondary zoospores in pathogenesis.

17

Table 1. Incidence of primary infection (root hair infection, RHI) on canola cv. Zephyr resulting from inoculation with resting spores (RS) and secondary zoospores (SZ) of pathotypes 3 (P3) and 6 (P6) of *Plasmodiophora brassicae*, assessed at 11, 13, and 15 days after seeding (DAS) (1, 3 and 5 days after inoculation with secondary zoospores).

Spore type & pathotype	Root hair infection (%)		
	11 DAS	13 DAS	15 DAS
RS-P6 (10 DAS) ¹	2 a ²	15 a	26 a
RS-P3 (10 DAS)	3 a	26 b	48 b
SZ-P6	4 a	32 c	55 c
SZ-P3	10 a	47 e	74 e
RS-P6	22 b	41 d	50 b
RS-P6+SZ-P3	35 c	55 f	60 d
RS-P3	46 d	64 g	72 e
RS-P3+SZ-P3	63 e	73 h	80 f
Standard error	0.44	1	0.7

¹The (10 DAS) treatments were inoculated with resting spores at the same time as the secondary zoospore treatments were applied. All other resting spore treatments were applied 5 DAS

²Values are the means of eight replications, with one plant per rep. Means within a column followed by the same letter do not differ at $P < 0.05$ based on Tukey's test.

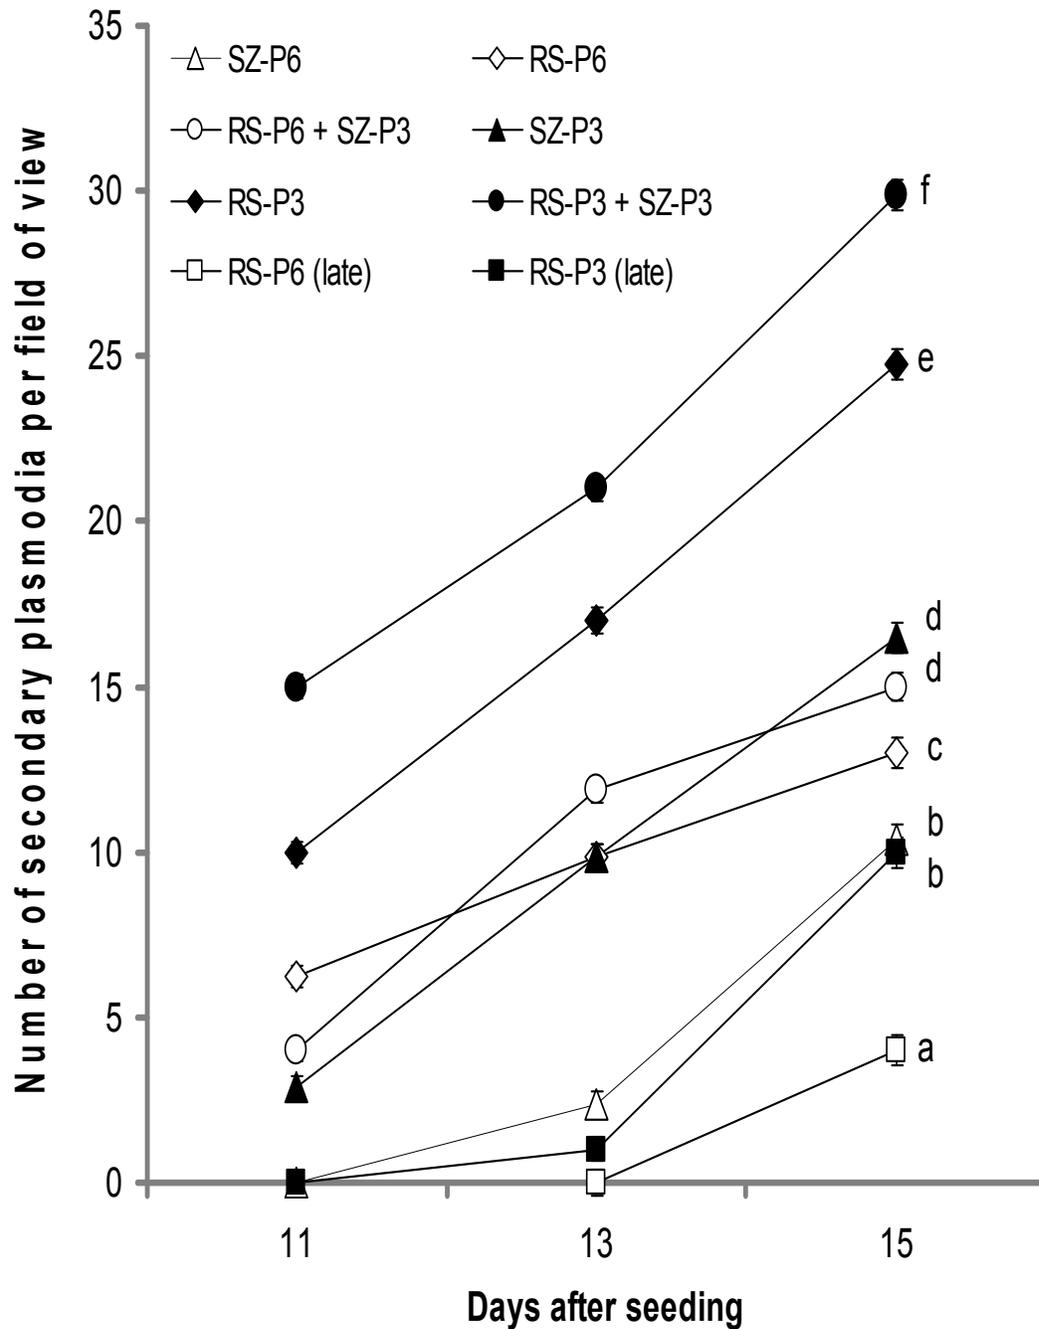

Fig. 1. Secondary infection (number of plasmodia per field of view) of canola 'Zephyr' at 1, 3, and 5 days after inoculation with resting sores or secondary zoospores'. The regression slopes among the treatments were similar therefore are not presented. Data points are the means of observed values of eight replications (one plant per rep). Means at 5 days after inoculation with the secondary zoospores followed by the same letter do not differ based on Tukey's test at $P \leq 0.05$. Capped lines = standard error.

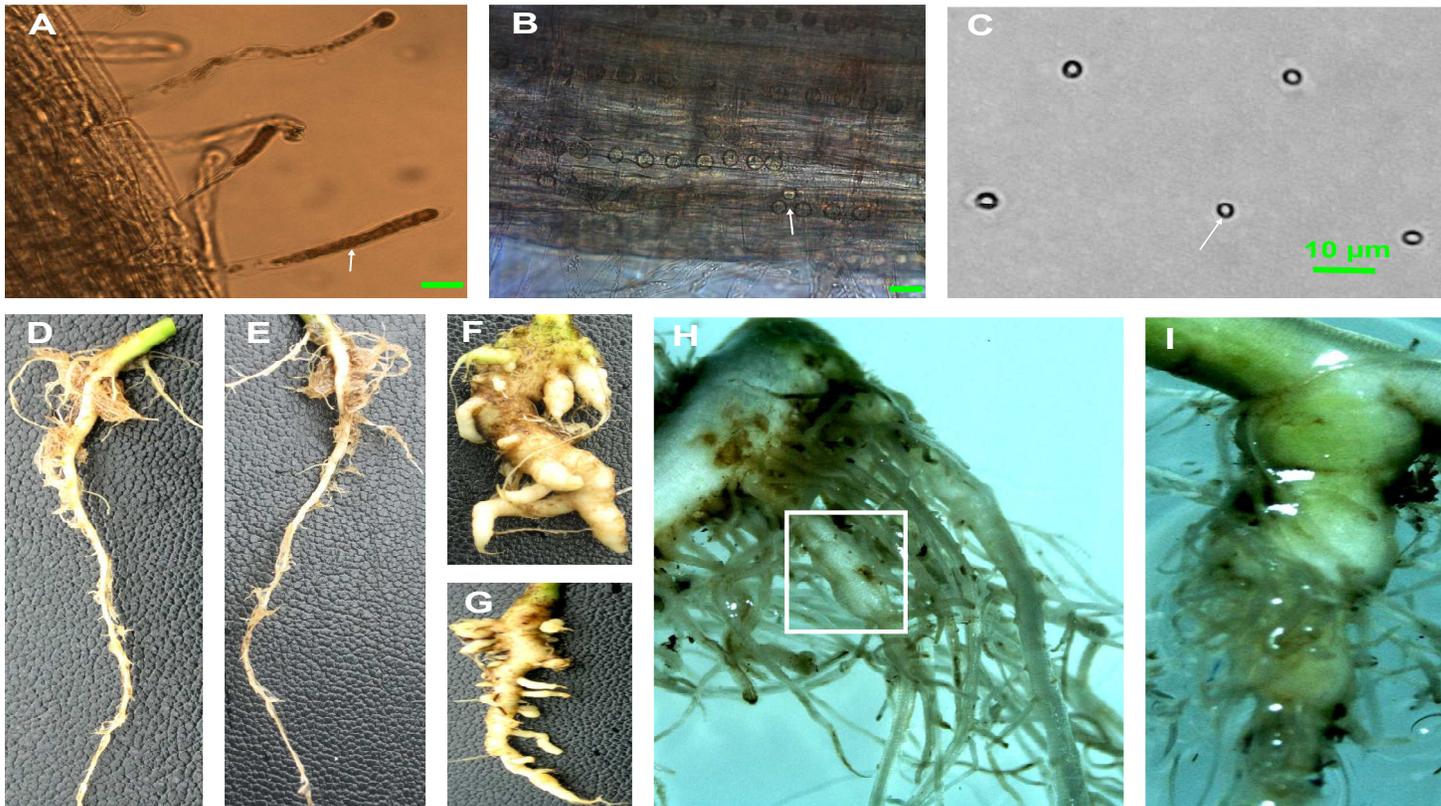

Fig. 2. (A) Infected root hair (arrow) and (B) young secondary plasmodia (arrow) on canola root inoculated with secondary zoospores of pathotype 6 (avirulent on cv. Zephyr) of *Plasmodiophora brassicae*. (C, D, E) Bead-shaped clubs from inoculation with secondary zoospores of pathotype 6.

Table 2. Clubroot severity on harvested roots, and area of cortical infection (%), number of infected cells with young plasmodia, mature plasmodia, or resting spores in five fields of view in sections of canola roots, and mean plant height (cm), shoot weight (g) and root weight (g) of canola cv. ‘Zephyr’, assessed at 52 days after seeding, which was 47 days after inoculation with resting spores (RS) and 42 days after inoculation with secondary zoospores (SZ) of pathotypes 3 (P3) and 6 (P6) of *Plasmodiophora brassicae*.

Spore type & pathotype	Number of infected cells						Plant growth parameters		
	Incidence (%)	Severity (%)	Area of cortical infection (%)	Young plasmodia	Mature plasmodia	Resting spores	Plant height (cm)	Shoot wt. (g)	Root wt. (g)
RS-P6	0 a ¹	0 a	0.1 a	22 d	0 a	0 a	49 c	4.0 c	1.1 a
SZ-P6	67 b	31 b	4 b	13 c	6 b	2 b	54 c	4.0 c	1.4 a
SZ-P3	78 c	67 c	12 c	6 b	12 d	12 c	28 b	3.0 b	2.2 b
RS-P6+ SZ-P3	85 c	84 d	18 d	1 a	15 e	26 d	28 b	2.6 b	2.2 b
RS-P3	100 d	100e	33 e	1 a	10 c	32 e	15 a	1.3 a	3.6 c
RS-P3+ SZ-P3	100 d	100 e	34 e	1 a	9 c	32 e	10 a	1.0 a	4.2 c
Control	0	0	0	0	0	0	50 c	4.6 c	1.1 a
Standard error	0.97	1.8	0.40	0.44	0.48	0.60	1.1	0.68	0.97

¹Values are the means of eight replications (10 plant per rep for incidence, severity and plant growth parameters, one plant and five fields of view per rep, for data on number of infected cells). Means in the columns followed by the same letter do not differ based on Tukey's test at $P \leq 0.05$.

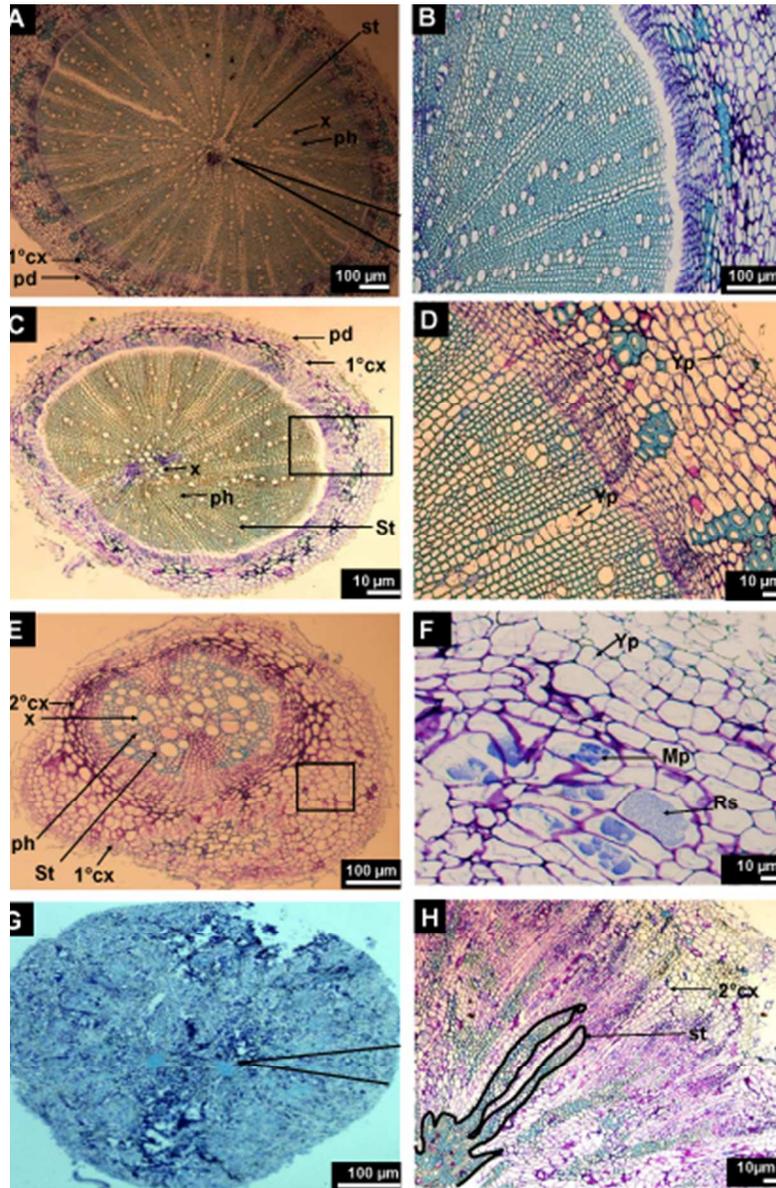

Fig. 3. Cross-section of roots of healthy and *P. brassicae*-infected canola plants, stained with TBO. (A) Healthy root (control). Lignified xylem cell walls stain dark blue, non-lignified walls are pink. (B) Magnified region from (A) showing intact stele, cortex and periderm. (C) Roots of plants inoculated with resting spores of pathotype 6 (avirulent on cv. Zephyr). (D) Magnified region from (C) showing intact stele, cortex and periderm (young plasmodia are marked with arrow). (E) Bead-shaped clubs produced after inoculation with secondary zoospores of P6. Note the proliferation of cortical tissue outside of the stele, and no proliferation within the stele. (F) Magnified region from (E) showing young plasmodia, mature plasmodia and resting in the cortical cells. (G) Typical clubs. Stele region is disrupted. (H) Magnified region from (G) showing invasion and expansion of stele (marked with black boundaries). Annotations: x, xylem; ph, phloem; 1° cx, primary cortex; 2° cx, secondary cortex; pd, periderm; st, stele.

146x222mm (72 x 72 DPI)

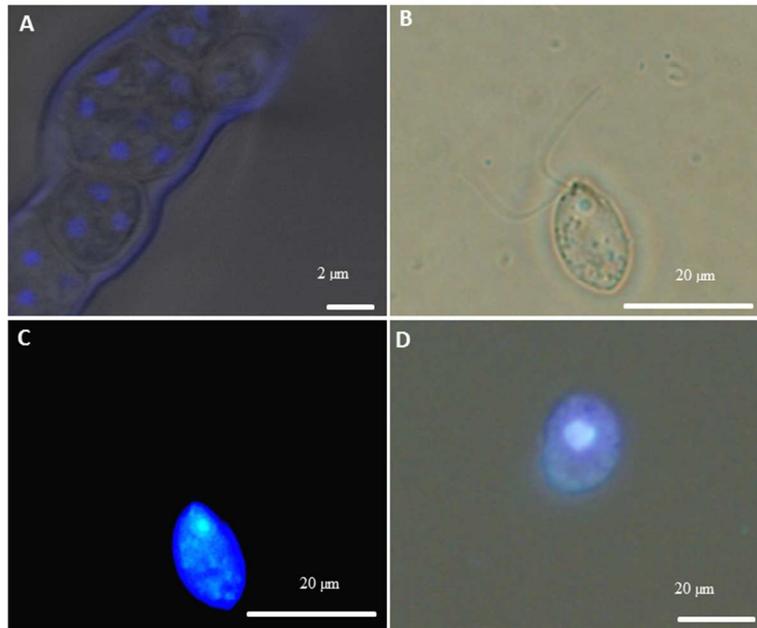

Fig. 4. Developmental stages and nuclear visualization in secondary zoospores (A) CLSM micrograph (overlaid fluorescence and DIC image) of an infected root hair stained with Hoechst 33258 showing the plasmodial mass cleaved into zoosporangia. Each zoosporangium contains a varying number (1 to 6) of nuclei that represent incipient secondary zoospores. (B) to (D) Epifluorescence micrographs. (B) Phase contrast of a bi-flagellated zoospore produced by mechanical shaking of root hairs. (C) Fluorescence image of DAPI staining of a single nucleus in the flagellated zoospore. (D) An overlaid image (fluorescence and phase contrast) of an encysted uni-nucleate zoospore (produced by centrifugation).
